\textbf{Abstract.} The proof system ∀-Exp+Res formally captures expansion-based solving of quantified Boolean formulas (QBFs) whereas the QRAT proof system captures QBF preprocessing. From previous work it is known that certain families of formulas have short proofs in QRAT but not in ∀-Exp+Res. However, it was not known if the two proof systems were incomparable (i.e., if there also existed QBFs with short ∀-Exp+Res proofs but without short QRAT proofs), or if QRAT polynomially simulates ∀-Exp+Res. We close this gap of the QBF-proof-complexity landscape by presenting a polynomial simulation of ∀-Exp+Res in QRAT. Our simulation shows how definition introduction combined with extended-universal reduction can mimic the concept of universal expansion.

\section{Introduction}

Proof systems for quantified Boolean formulas (QBFs) have been extensively studied to obtain a better understanding of the strengths and limitations of different QBF-solving approaches (e.g., [5, 10, 8, 3, 13, 25]). Much is known about instantiation-based proof systems [16, 4, 5], which provide the foundation for expansion-based solvers [15, 7], and about Q-resolution systems [13, 20, 28, 1, 26, 2, 6, 14, 23], which provide the foundation for search-based solvers [21, 22]. There is, however, one other practically useful proof system that is quite different from the aforementioned ones and whose exact place in the complexity landscape is still unclear: the QRAT proof system [12].

The QRAT proof system is a generalization of DRAT [27] (the de-facto standard for proofs in practical SAT solving) that has its strengths when it comes to preprocessing: Many QBF solvers benefit from preprocessing techniques to simplify a QBF before they actually evaluate its truth. With the QRAT system, it is possible to certify the correctness of virtually all preprocessing simplifications performed by state-of-the-art QBF solvers and preprocessors. Recently, it has been shown that QRAT can polynomially simulate the long-distance-resolution calculus, a strictly stronger extension of the Q-Resolution calculus [18]. So far, however, it has not been known if QRAT can also polynomially simulate the instantiation-based calculus ∀-Exp+Res [16]. In this short paper, we show that this is indeed the case by providing a simulation whose resulting QRAT proof is only linear in the size of the original ∀-Exp+Res proof.

2 Preliminaries

We consider quantified Boolean formulas in prenex conjunctive normal form (PCNF), which are of the form \( \mathcal{Q} \psi \), where \( \mathcal{Q} \) is a quantifier prefix and \( \psi \), called the matrix of the QBF, is a propositional formula in conjunctive normal form (CNF); we define propositional formulas and quantifier prefixes in the following.

Propositional formulas in CNF are built from variables and logical operators as follows. A literal is either a variable \( x \) (a positive literal) or the negation \( \bar{x} \) of a variable \( x \) (a negative literal). The complement \( \bar{l} \) of a literal \( l \) is defined as \( \bar{l} = \bar{x} \) if \( l = x \) and \( \bar{l} = x \) if \( l = \bar{x} \). A clause is a finite disjunction of the form \( (l_1 \lor \cdots \lor l_m) \) where \( l_1, \ldots, l_m \) are literals. We denote the empty clause by \( \bot \). A clause with exactly one literal is a unit clause. A formula is a finite conjunction of the form \( C_1 \land \cdots \land C_m \) where \( C_1, \ldots, C_m \) are clauses. Clauses can be viewed as sets of literals, and formulas can be viewed as sets of clauses. For an expression (i.e., a literal, formula, etc.) \( E \), we denote the set of variables occurring in \( E \) by \( \text{var}(E) \). If \( \text{var}(E) \) is a singleton set, we sometimes treat it like a variable.

A quantifier prefix has the form \( Q_1 X_1 \cdots Q_q X_q \) where all the \( X_i \) are mutually disjoint sets of variables, \( Q_i \in \{\forall, \exists\} \), and \( Q_i \neq Q_{i+1} \). The quantifier of a literal \( l \) is \( Q_i \) if \( \text{var}(l) \in X_i \). Given a literal \( l \) with quantifier \( Q_i \) and a literal \( k \) with quantifier \( Q_j \), we write \( l \leq_Q k \) if \( i \leq j \) and \( l <_Q k \) if \( i < j \). We sometimes write \( l \leq k \) instead of \( l \leq_Q k \), and we write \( l < k \) instead of \( l <_Q k \) if \( Q \) is clear from the context. If \( l \leq k \), we say that \( l \) occurs left of \( k \).

Given a literal \( l \) and a propositional formula \( \psi \), we define \( \psi[l] \) to be the formula obtained from \( \psi \) by first removing all clauses that contain \( l \) and then removing \( \bar{l} \) from all remaining clauses. The result of applying the unit-clause rule to \( \psi \) is the formula \( \psi[l] \) where \( (l) \) is a unit clause in \( F \). The iterated application of the unit-clause rule, until either the empty clause is derived or no unit clauses are left, is called unit propagation. In case unit propagation derives the empty clause, we say that unit propagation derived a conflict on \( \psi \).

Given a propositional formula \( \psi \) and a clause \( (l_1 \lor \cdots \lor l_k) \), we say that \( \psi \) implies \( (l_1 \lor \cdots \lor l_k) \) via unit propagation—denoted by \( \psi \vdash (l_1 \lor \cdots \lor l_k) \)—if unit propagation derives a conflict on \( \psi \land (l_1) \land \cdots \land (l_k) \). For example, the formula \( (x \lor z) \land (\bar{y} \lor \bar{z}) \) implies the clause \( (x \lor \bar{y}) \) via unit propagation since unit propagation derives a conflict on \( (x \lor z) \land (\bar{y} \lor \bar{z}) \land (x) \land (y) \).

A QBF \( \exists x \mathcal{Q} \psi \) is true if at least one of \( \mathcal{Q} \psi[x] \) and \( \mathcal{Q} \psi[\bar{x}] \) is true, otherwise it is false. Respectively, a QBF \( \forall x \mathcal{Q} \psi \) is true if both \( \mathcal{Q} \psi[x] \) and \( \mathcal{Q} \psi[\bar{x}] \) are true, otherwise it is false. If the matrix \( \psi \) of a QBF \( \mathcal{Q} \psi \) is the empty formula, then \( \mathcal{Q} \psi \) is true. If \( \phi \) contains the empty clause, then \( \mathcal{Q} \psi \) is false.

An assignment is a function from variables to the truth values 1 (true) and 0 (false). We denote assignments by the sequences of literals they satisfy. E.g., \( x\bar{y} \) denotes the assignment that assigns 1 to \( x \) and 0 to \( y \).

Finally, for the formal definition of polynomial simulations between proof systems we refer to Cook and Reckhow [9]. An informal summary is this: A proof system \( f \) polynomially simulates a proof system \( g \) if there exists a polynomial-time procedure that transforms \( g \)-proofs into \( f \)-proofs.
3 The QRAT Proof System

Here, we introduce the basics of the QRAT proof system [12]. The two main concepts behind QRAT are QRAT literals and universal reduction via the reflexive-resolution-path dependency scheme [11].

The definition of QRAT literals is based on the notion of an outer resolvent. Given two clauses $C \lor l, D \lor \bar{l}$ of a QBF $Q, \psi$, the outer resolvent $C \lor l \rightarrow_{Q}^O D \lor \bar{l}$ of $C \lor l$ with $D \lor \bar{l}$ upon $l$ is the clause consisting of all literals in $C$ together with those literals of $D$ that occur left of $l$, i.e., the clause $C \lor \{k \mid k \in D \text{ and } k \leq_{Q} l\}$. If all outer resolvents upon a literal are implied via unit propagation, then that literal is a QRAT literal [12]:

**Definition 1.** A literal $l$ is a QRAT literal in a clause $C \lor l$ with respect to a QBF $Q, \psi$ if, for every clause $D \lor \bar{l} \in \psi \setminus \{C \lor l\}$, it holds that $\psi \models C \lor l \rightarrow_{Q}^O D \lor \bar{l}$.

**Example 1.** Let $C = (b \lor x \lor y)$ and let $\phi = \exists a \forall x Q \exists c. (b \lor \bar{y} \lor c) \land (a \lor \bar{y} \lor c) \land (a \lor b \lor x)$, where $Q \in \{\exists, \forall\}$. The literal $y$ is a QRAT literal in $C$ with respect to $\phi$ since there are two outer resolvents: the tautology $(b \lor \bar{b} \lor x)$, obtained by resolving with $(b \lor \bar{y} \lor c)$, and the clause $(a \lor b \lor x)$, obtained by resolving with $(a \lor \bar{y} \lor c)$. The matrix of $\phi$ implies both outer resolvents via unit propagation.

Let $\phi = Q, \psi$ be a QBF. If a universal literal $u$ is a QRAT literal in a clause $C \in \psi$, the removal of $u$ from $C$ is called QRAT-literal elimination. If, after adding a universal literal $u$ to a clause $C \in \psi$, $u$ becomes a QRAT literal, then this addition is called QRAT-literal addition. If a clause contains an existential QRAT literal, it is called a QRAT clause (or simply a QRAT) with respect to $\phi$: its addition to a QBF is called QRAT addition and its removal is called QRAT elimination. It can be shown that QRAT-literal addition and elimination as well as QRAT-clause addition and elimination preserve the truth value of a QBF.

The introduction of definition clauses of the form $(x \lor y), (x \lor \bar{y})$ (where $x$ is a fresh variable not occurring in $\phi$), is an instance of QRAT addition if we put $x$ into the same quantifier block as $y$: $(x \lor y)$ is a QRAT since $x$ is fresh and thus there are no outer resolvents upon $x$; $(x \lor \bar{y})$ is then a QRAT since the only outer resolvent upon $x$ is the tautology $(\bar{y} \lor y)$, obtained by resolving with $(x \lor y)$.

The reflexive-resolution-path dependency scheme (short, $D^{rrs}$) is based on the notion of a resolution path [11]. Intuitively, a QBF contains a resolution path between a universal literal $u$ and an existential literal $e$ if we can start with a clause that contains $u$ and perform a number of resolution steps over existential literals that occur right of $u$ to obtain a clause that contains both $u$ and $e$. An example of a resolution path is given in Fig. 1.

![Fig. 1. A resolution path from $u$ to $e_4$.](image-url)
Definition 2. Given a QBF $\phi = Q\psi$, a universal literal $u$, and an existential literal $e_n$, $\phi$ contains a resolution path from $u$ to $e_n$ if there exists a sequence $C_1, \ldots, C_n$ of clauses and a sequence $e_1, \ldots, e_{n-1}$ of existential literals such that

1. $u \in C_1$ and $e_n \in C_n$,
2. $e_1, \ldots, e_n$ occur right of $u$,
3. $e_i \in C_i$, $\bar{e}_i \in C_{i+1}$, for $i = 1, \ldots, n-1$, and
4. $\text{var}(e_i) \neq \text{var}(e_{i+1})$ for $i = 1, \ldots, n-1$.

The reflexive-resolution-path dependency scheme defines that a literal $e$ depends on a literal $u$ if and only if $e$ is existential, $u$ is universal, and at least one of the following conditions holds: (1) There exist resolution paths from $u$ to $e$ and from $\bar{u}$ to $\bar{e}$. (2) There exist resolution paths from $u$ to $\bar{e}$ and from $\bar{u}$ to $e$.

Next we define the QRAT proof system. In the QRAT proof system, a derivation for a QBF $\phi = Q\psi$ is a sequence $M_1, \ldots, M_n$ of proof steps. Starting with $\phi_0 = \phi$, every $M_i$ modifies $\phi_{i-1}$ in one of the following five ways, which results in a new formula $\phi_i = Q_1, \psi_i$, which we call the accumulated formula at step $i$:

1. Add a clause that is implied by $\psi_{i-1}$ via unit propagation.
2. Add a clause that is a QRAT clause with respect to $\phi_{i-1}$.
3. Remove an arbitrary clause from $\phi_{i-1}$.
4. Remove a QRAT literal from a clause in $\phi_{i-1}$.
5. Remove a universal literal $u$ from a clause $C \land u \in \phi_{i-1}$ where all $l \in C$ are independent of $u$ according to $D^{\text{rrs}}$ ("extended universal reduction").

A QRAT derivation $M_1, \ldots, M_n$ thus derives new formulas $\phi_1, \ldots, \phi_n$ from $\phi$. If the final formula $\phi_n$ contains $\bot$, then the derivation is a (refutation) proof of $\phi$. To simplify the presentation, we do not specify in detail how the modification steps $M_i$ are represented syntactically, but it should be clear that their size needs to be at most linear with respect to the involved clauses and literals. Note that certain proof steps can modify the quantifier prefix.

4 The $\forall$-Exp+Res Proof System

A $\forall$-Exp+Res proof of a QBF $\phi = Q\psi$ is a sequence $C_1, \ldots, C_n$ of clauses where each clause is obtained either via the axiom rule or the resolution rule. The axiom rule is as follows:

$$\frac{C}{\{l^n \mid l \in C, l \text{ is existential}\}} \quad \text{(Ax)}$$

Here, $C$ is a clause of $\psi$, $\tau$ is an assignment that falsifies all universal literals of $C$, and $\tau_l$ denotes the assignment $\tau$ restricted to the universal variables $u$ with $u < l$. Intuitively, $\tau_l$ can be seen as an annotation of the literal $l$. For example, the axiom rule allows us to use the assignment $\tau = uv$ for deriving the clause $x^u \lor y^{uv}$ from the formula $\forall u \exists x \forall v \exists y. (\bar{u} \lor x \lor v \lor \bar{y})$. The resolution rule of $\forall$-Exp+Res is just the usual resolution rule from propositional logic—it derives a new clause $C_k$ from two earlier clauses $C_i, C_j$ with $i, j < k$: 

4
We next illustrate the intuition behind the simulation of ∀-Exp+Res by QRAT.

5 Simulating ∀-Exp+Res by QRAT: Intuition

To simulate ∀-Exp+Res by QRAT, we need to find a way to simulate applications of the axiom rule. Intuitively, the axiom rule introduces multiple instantiations of a single existential variable because, in satisfying assignments of the formula, this variable might take different truth values depending on the truth values of the universal variables that occur left of it. We can introduce these instantiations in QRAT by first adding definitions of the new variables and then eliminating the superfluous universal variables with extended-universal reduction. Once this is done, we can just straightforwardly perform the remaining resolution steps in QRAT since resolvents are implied via unit propagation. Assume a ∀-Exp+Res proof uses the axiom rule as follows, where the quantifier prefix is ∀u∃x∀v∃y:

\[
\overline{u} ∨ x ∨ v ∨ y
\]

We simulate the derivation of \( (x^u ∨ y^u) \) in QRAT as follows:

1. Add definitions for the new variables \( x^u \) and \( y^u \), where \( x^u \) goes to the same quantifier block as \( x \) and \( y^u \) goes to the same quantifier block as \( y \).
   The new clauses are \( (\overline{x} ∨ x^u) \), \( (x ∨ \overline{x}^u) \), \( (\overline{y} ∨ y^u) \), \( (y ∨ \overline{y}^u) \).
2. Add a clause that is similar to the original clause \( (\overline{u} ∨ x ∨ v ∨ y) \), with the only difference that we now use the new annotated variables instead of the original ones. Observe that we can resolve \( (\overline{u} ∨ x ∨ v ∨ y) \) with \( (\overline{u} ∨ x^u ∨ v ∨ y^u) \) to replace \( x \) by \( x^u \); likewise for \( y \) and \( y^u \). Because of this, \( (\overline{u} ∨ x^u ∨ v ∨ y^u) \) and the definition clauses together imply the new clause, \( (\overline{u} ∨ x^u ∨ v ∨ y^u) \), via unit propagation.
3. Eliminate \( (\overline{u} ∨ x ∨ v ∨ y) \) and the definition clauses introduced in step 1.
4. Eliminate the universal literals \( \overline{u} \) and \( v \) from \( (\overline{u} ∨ x^u ∨ v ∨ y^u) \) by extended universal reduction, resulting in the clause \( (x^u ∨ y^u) \).

The correctness of the fourth step is a consequence of Lemma 1, which we prove in the next section, where we define our simulation.

6 Simulating ∀-Exp+Res by QRAT

We start with a QBF \( Q,\psi \) and a ∀-Exp+Res proof \( \pi \) of \( Q,\psi \). We then construct a QRAT proof \( \Pi \) of \( Q,\psi \) as follows:

Step 1 (Introduction of Definitions): For each annotated variable \( x^\tau \) in the ∀-Exp+Res proof \( \pi \), we introduce a definition of the form \( (\overline{x} ∨ x^\tau), (x ∨ \overline{x}^\tau) \). We also put \( x^\tau \) into the same quantifier block as \( x \). Note that each annotated
variable must have been obtained by an application of the axiom rule. The
definition introductions are QRAT additions, as explained on page 3. We denote
the resulting accumulated formula by \( Q'.\psi_1 \).

**Step 2 (Introduction of Annotated Clauses):** For each clause \( C^r \in \pi \) that
was obtained from a clause \( C \in \psi \) by applying the axiom rule with the assign-
ment \( \tau \), we add the clause \( C^r \lor \bar{u}_1 \lor \cdots \lor \bar{u}_k \). Since \( C \) and the definitions of
the annotated literals of \( C^r \) are in \( \psi_1 \), the clause \( C^r \lor \bar{u}_1 \lor \cdots \lor \bar{u}_k \) is implied via unit
propagation and thus it can be added as a QRAT. We denote the accumulated
formula after performing all these QRAT additions by \( Q'.\psi_2 \).

**Step 3 (Elimination of Input Clauses and Definitions):** We now eliminate
all clauses of \( \psi \) as well as the definitions introduced in step 1 since we don’t need
them anymore. Note that QRAT allows the elimination of arbitrary clauses. We
thus obtain the accumulated formula \( Q'.\psi_3 \) with \( \psi_3 := \psi_2 \setminus \psi_1 \).

**Step 4 (Removal of Universal Literals):** We now remove all universal literals
from the clauses in \( \psi_3 \). We start by removing the occurrences of the right-most
variable \( u \) and apply extended universal reduction on all clauses in which it
occurs. Once \( u \) is eliminated, we move on to the new right-most variable and
eliminate it. We also remove eliminated variables from the quantifier prefix. We
repeat this for all universal literals and denote the resulting accumulated formula
by \( Q'.\psi_4 \). It remains to show that all the removal steps are valid extended-
universal-reduction steps. This is a consequence of the following lemma:

**Lemma 1.** If \( Q'.\psi_3 \) contains a resolution path from \( u \) to \( e \), then \( e \) must be an
annotated literal of the form \( l^r \) where the assignment \( \tau \) falsifies \( u \).

**Proof.** Suppose there exists a resolution path \( C_1, \ldots, C_n \) from \( u \) to \( e \). We show
by induction on \( n \) that \( e \) is of the form \( l^r \) where \( \tau \) falsifies \( u \).

**Base Case** \((n = 1): C_1 \) contains both \( u \) and \( e \). Hence, all the existential literals
of \( C_1 \) must have been obtained by instantiating with an assignment that falsifies
all universal literals of \( C_1 \). Moreover, by the definition of resolution paths, \( e \) must
occur right of \( u \). Hence, \( e \) must be of the form \( l^r \) where \( \tau \) falsifies \( u \).

**Induction Step** \((n > 1): Since C_1, \ldots, C_n \) is a resolution path from \( u \) to \( e \), we
know that \( e \in C_n \) and that \( C_1, \ldots, C_{n-1} \) is a resolution path from \( u \) to some
l literal \( e_{n-1} \) such that \( e_{n-1} \in C_{n-1} \) and \( e_{n-1} \in C_n \). By the induction hypothesis,
\( e_{n-1} \) is of the form \( l_{n-1}^r \) where \( \tau \) falsifies \( u \). But then, since \( e_{n-1} \in C_n \), we know
that \( C_n \) must have been obtained by instantiating it with an assignment that
falsifies \( u \). It follows that \( e \) is of the form \( l^r \) where \( \tau \) falsifies \( u \). \( \square \)

Thus, whenever we eliminate a universal literal \( u \) from a clause \( C \) in step 4,
then \( D^{\text{trs}} \) defines each existential literal \( e \in C \) that occurs right of \( u \) to be
independent of \( u \) (literals to the left of \( u \) are trivially independent of \( u \)): Since
\( e \in C \), we know that \( e \) is of the form \( l^r \) where \( \tau \) falsifies \( u \). Thus, there cannot
exist resolution paths from \( \bar{u} \) to \( e \) or to \( \bar{e} \), for otherwise Lemma 1 would tell us
that \( e \) is of the form \( l^r \) where \( \sigma \) falsifies \( \bar{u} \). Hence, \( e \) is independent of \( u \) according
to \( D^{\text{trs}} \). Note that, strictly speaking, Lemma 1 would only guarantee that the
first elimination of a universal literal is a valid extended-universal-reduction step (because the elimination modifies the formula $Q',\psi_3$). However, since the elimination of universal literals does not introduce additional resolution paths, all eliminations of universal literals are valid extended-universal-reduction steps.

**Step 5 (Resolution Proof):** In this last step, we perform all resolution steps of $\pi$ as QRAT additions to derive the empty clause. This is possible since $\psi_4$ contains all clauses that are involved in the resolution proof. We thus conclude:

**Theorem 2.** $\Pi$ is a QRAT refutation of $Q,\psi$.

We illustrate our simulation on an example before showing that it is polynomial:

**Example 2.** Fig. 2 shows a $\forall$-Exp+Res refutation of $\exists a \forall x \exists b \forall y \exists c.\psi$ with

$$\psi = (a \lor x \lor b \lor y \lor c) \land (a \lor x \lor b \lor y \lor \bar{c}) \land (x \lor \bar{b}) \land (\bar{y} \lor c) \land (\bar{a} \lor \bar{x} \lor b \lor \bar{c}) \land (\bar{x} \lor \bar{b}).$$

For simulating this proof in QRAT, we proceed as follows.

(1) We introduce definitions of the annotated variables by adding the following eight QRAT clauses:

$$\begin{align*}
(\bar{b} \lor \bar{x}) & \quad (\bar{b} \lor \bar{x}) \\
(\bar{b} \lor \bar{x}) & \quad (\bar{b} \lor \bar{x}) \\
(c \lor \bar{x}) & \quad (c \lor \bar{x}) \\
(c \lor \bar{x}) & \quad (c \lor \bar{x})
\end{align*}$$

(2) We then introduce the following QRAT clauses, which correspond to applications of the axiom rule in $\forall$-Exp+Res:

$$\begin{align*}
(a \lor x \lor b \lor y \lor \bar{c}) & \quad (\bar{y} \lor \bar{c}) \\
(a \lor x \lor b \lor y \lor \bar{c}) & \quad (\bar{y} \lor \bar{c}) \\
(x \lor \bar{b}) & \quad (x \lor \bar{b})
\end{align*}$$

(3) We remove the original clauses and the clauses introduced in step 1. Only the clauses introduced in step 2 remain.

(4) From the remaining clauses, we first remove all occurrences of $y$ and then all occurrences of $x$ via extended universal reduction. We obtain the clauses introduced by applications of the axiom rule in the $\forall$-Exp+Res proof.

(5) Finally, we can simply perform the resolution steps of the $\forall$-Exp+Res proof to obtain a QRAT refutation of the input formula.

This concludes the example. \qed
It remains to show that the simulation is polynomial. We first bound the size (measured by the number of symbols) of the resulting QRAT proof:

**Lemma 3.** $\Pi$ is linear in the size of $\pi$.

**Proof.** In step 1 (definition introduction), we perform two QRAT additions for each annotated variable in the $\forall$-Exp+Res proof $\pi$. The size of the corresponding QRAT derivation is clearly linear with respect to $\pi$. In step 2, we perform one QRAT addition for each application of the axiom rule in $\pi$, again resulting in a linear-size QRAT derivation. In step 3, we eliminate clauses of $\psi$ and definitions—also clearly linear. In step 4, we remove universal literals from existing clauses. All these universal literals are contained in $\pi$ as their respective clauses are involved in applications of the axiom rule. Hence, also this step yields a QRAT derivation of linear size. Finally, the resolution proof derived in step 5 is part of $\pi$ and thus also of linear size with respect to $\pi$. We conclude that the size of the final QRAT proof is linear with respect to the size of $\pi$. \qed

It should now be clear that our simulation can be performed in polynomial time:

**Theorem 4.** QRAT polynomially simulates $\forall$-Exp+Res.

## 7 Conclusion

We filled an empty spot in the QBF-proof-complexity landscape by showing that QRAT polynomially simulates universal expansion in general, and the proof system $\forall$-Exp+Res in particular. Our approach is similar to the approach in [12], which mimics the expansion of inner-most universal variables in QRAT.

There are, however, some subtle but important differences to [12]. First, in [12] the universal variables are fully expanded, which could potentially duplicate the whole formula. In contrast, we expand arbitrary variables and focus only on the clauses that are used as axioms in the $\forall$-Exp+Res proof. By only deriving these clauses (using new definitions), we can ensure that the resulting proof is small. Second, in [12] the QRAT proof is generated during proof search, when it is still unclear if the formula is true or false. In our simulation here, the proof of unsatisfiability is given as input and therefore we know from the beginning that the formula is false. This allows us to delete clauses eagerly (deletion doesn’t have to preserve satisfiability), which is not the case in [12].

A closer look at our simulation shows that the only features of QRAT needed for the simulation are Q-resolution, definition introduction, and extended universal reduction. A system that uses only these features could be seen as extended $Q(D_{\text{res}})$-resolution in the dependency framework of Slivovsky and Szeider [24].

In propositional logic, we know that extended resolution polynomially simulates DRAT [19] but it is not known if extended Q-resolution [17] or extended $Q(D_{\text{res}})$-resolution can polynomially simulate QRAT. It is also still unclear how QRAT is related to the stronger expansion-based systems IR-calc and IRM-calc [4]. Finally, since there exist efficient proof checkers for QRAT and since the size increase induced by our simulation is only linear, our simulation could be used in practice to validate the results of expansion-based solvers.
